The Global Impact of Tariff Escalation: A Trade War Simulation

Executive Summary

This report presents findings from a simulation examining the potential global impacts of aggressive tariff policies, similar to those implemented in recent years. The key discoveries include:

- **Emergence of a "Trade War Spiral"**: The simulation reveals a self-reinforcing cycle where initial tariff increases trigger retaliatory responses, leading to escalating protectionism over time. This pattern emerges organically from the economic relationships in the model.
- **Universal Economic Damage**: All participating economies suffer significant economic harm, with GDP levels declining by 63-75% over the 20-quarter simulation period. Notably, major economies experience proportionally larger GDP declines than their smaller trading partners.
- **Declining Trade Volumes**: Global trade activity contracts by approximately 29%, reducing economic efficiency and growth opportunities across all simulated economies.
- **Stagflationary Pressure**: Despite declining economic activity, inflation rates in major economies steadily increase, creating a challenging policy environment of stagnant growth with rising prices.
- **Growing Policy Volatility**: Tariff adjustment decisions become increasingly extreme over time, with major economies showing particularly large swings between aggressive increases and desperate reductions.

The simulation demonstrates that despite the appeal of tariffs as tools to address perceived trade imbalances or protect specific industries, their broader implementation can trigger systemic responses that ultimately harm all economies involved. The results strongly suggest that international coordination mechanisms and policy constraints are essential to prevent destructive trade war dynamics from taking hold.

Introduction

In recent years, international trade relations have been marked by periods of increasing protectionism, with tariff policies becoming a central tool in economic diplomacy. This simulation explores how the imposition of tariffs by major economies can impact global trade dynamics, GDP growth, and inflation. The analysis is particularly relevant in understanding the potential consequences of aggressive tariff policies similar to those implemented during the Trump administration and potential similar policies in the future.

The simulation seeks to answer several key questions: 1. How do tariff increases

by major economies affect their own economic indicators? 2. How do trading partners respond to these tariff changes? 3. What are the cumulative effects of these interactions on global trade volume? 4. Could these dynamics lead to a self-reinforcing trade war with negative consequences for all participants?

By modeling the dynamic interactions between major economies and their trading partners over time, we gain insights into the complex feedback mechanisms that operate in international trade.

Model Description

The simulation employs an agent-based modeling approach with two distinct groups of economic agents:

1. **Major Economies** (3 agents): Representing large economic powers with significant global influence, analogous to entities like the United States, European Union, and China. These agents have memory of the past 4 periods to inform their decisions.

2. **Trading Partners** (5 agents): Representing smaller but still significant economies that engage in substantial trade with the major powers. These agents have shorter memory spans (2 periods), reflecting potentially more reactive policy approaches.

Each agent is characterized by key economic variables:

- **GDP Level**: An index starting at 100, representing the overall economic output.
- **Tariff Rate**: The average effective tariff rate applied to imports, starting at 2%.
- **Trade Volume**: An index starting at 100, representing the total volume of international trade.
- **Inflation Rate**: (Major economies only) The annual rate of price increases, initially set at 2%.

The agents can take the following actions:

- **Adjust Tariffs**: Major economies can adjust their tariff rates by -10 to +25 percentage points per quarter, while trading partners can adjust by -5 to +15 percentage points.

The model implements several key economic relationships:

1. **GDP Growth**: Higher tariffs (both domestic and foreign) negatively impact GDP growth.
2. **Trade Volume**: Increases in tariff rates lead to logarithmic decreases in trade volumes.
3. **Inflation**: For major economies, inflation increases with higher tariffs and decreases with higher trade volumes.

These relationships create feedback loops where tariff increases can trigger retaliatory responses, potentially leading to declining economic performance across all participants.

Simulation Setup

The simulation was conducted over a period of 20 quarters (5 years), with each step representing one quarter. This timeframe allows sufficient time to observe both immediate reactions to tariff changes and longer-term economic consequences.

The initial conditions were set as follows: - All economies began with a GDP level index of 100 - Initial tariff rates were set at 2% for all agents - Trade volume indices started at 100 - Inflation rates for major economies started at 2%

The simulation captures the dynamic decision-making of these economic agents as they respond to changing conditions. Major economies (with longer memory) can make more strategic moves based on a longer historical view, while trading partners (with shorter memory) tend to respond more directly to recent developments.

No explicit coordination mechanisms were included between agents, meaning that each economy makes its tariff decisions independently based on its own assessment of the situation. This reflects the often uncoordinated nature of international trade policy, especially during periods of increased protectionism.

Economic indicators (GDP, trade volume, inflation, and tariff rates) were tracked at each quarterly interval to analyze both short-term fluctuations and longer-term trends across all participating economies.

Results

The simulation results reveal several key patterns in economic performance and policy responses over the 20-quarter period. The following figures illustrate these patterns.

GDP Trends

Figure 1 shows the GDP levels for major economies over time, revealing a consistent downward trajectory.

Figure 1: GDP level trends for major economies over 20 quarters. The index shows a steady decline from the starting value of 100 to approximately 25 by the end of the simulation period, representing a 75% reduction in economic output.

Similarly, trading partners experienced comparable GDP declines over the same period:

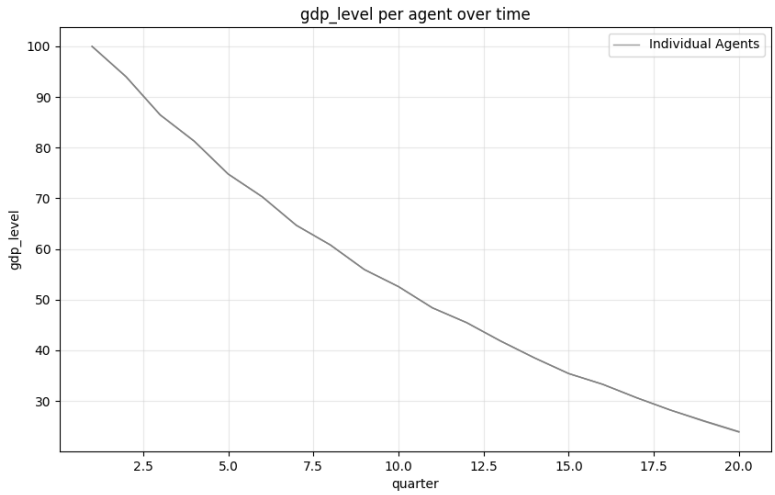

Figure 1: major_economies_gdp_level

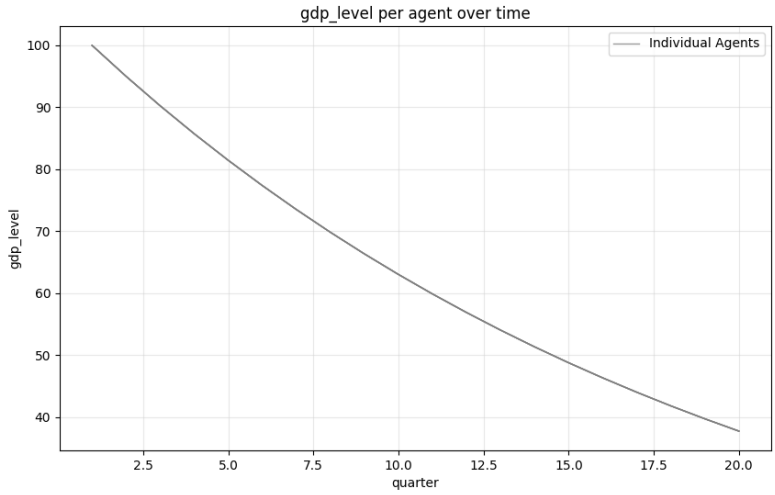

Figure 2: trading_partners_gdp_level

Figure 2: GDP level trends for trading partners over 20 quarters. The pattern closely mirrors that of major economies, with a decline from 100 to approximately 37, representing a 63% reduction.

Tariff Rate Dynamics

The tariff rates applied by both major economies and trading partners fluctuated significantly throughout the simulation:

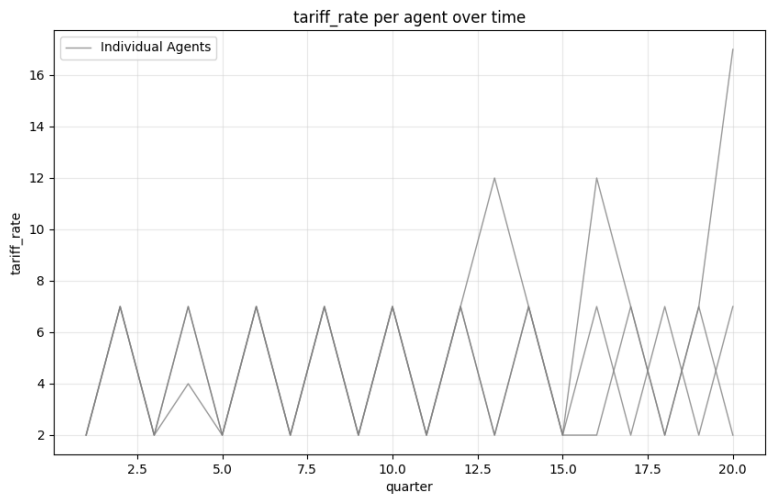

Figure 3: major_economies_tariff_rate

Figure 3: Tariff rates for major economies over time. The rates show increasingly volatile patterns with regular oscillations. Starting from an initial 2% level, spikes reached as high as 17% in later quarters, with growing amplitude over time.

Figure 4: Tariff rates for trading partners over time. While exhibiting similar oscillatory behavior, these rates generally remained lower than those of major economies, mostly fluctuating between 2% and 6%, with one exceptional spike to about 6%.

Trade Volume Trends

Trade volumes declined steadily for both groups of economies:

Figure 5: Trade volume for major economies over time. The index shows a steady decline from 100 to approximately 71, representing a 29% reduction in trade activity.

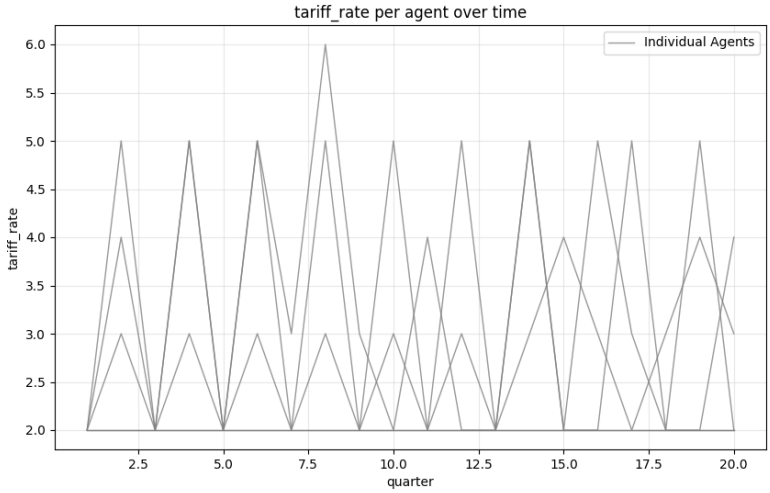

Figure 4: trading_partners_tariff_rate

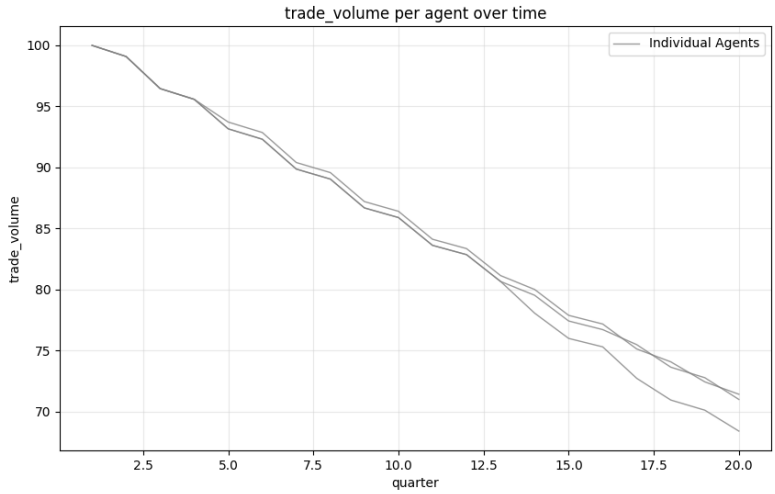

Figure 5: major_economies_trade_volume

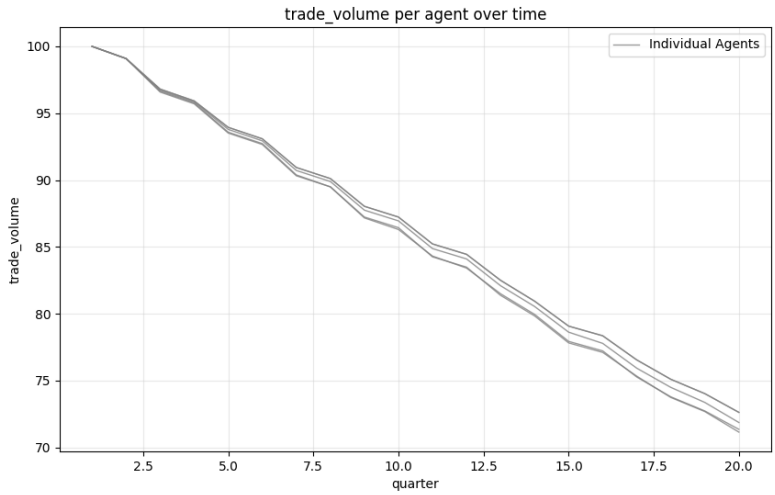

Figure 6: trading_partners_trade_volume

Figure 6: Trade volume for trading partners over time. These economies experienced a similar pattern of decline, ending at approximately 72 (28% reduction).

Inflation and Policy Responses

For major economies, inflation showed a steady upward trend despite declining economic activity:

Figure 7: Inflation rates for major economies over time. Starting from 2%, inflation increased steadily with growing volatility, reaching near 2.4% by the end of the simulation.

The tariff adjustment decisions made by both groups reveal the policy responses:

Figure 8: Tariff adjustment decisions by major economies. The pattern shows increasingly extreme swings between positive adjustments (tariff increases) and negative adjustments (tariff decreases), with the amplitude growing over time.

Figure 9: Tariff adjustment decisions by trading partners. While less extreme than major economies, these adjustments still show oscillatory behavior, suggesting reactive policy responses.

These results collectively illustrate a troubling pattern of economic decline accompanied by policy volatility, suggesting a trade war dynamic with significant negative consequences.

Analysis and Discussion

The simulation results reveal several critical insights into the dynamics of international trade relations and the potential consequences of aggressive tariff policies.

Emergence of a Trade War Spiral

The most striking finding is the clear emergence of a "trade war spiral" – a self-reinforcing cycle of retaliatory tariff increases that leads to significant economic damage for all participants. This dynamic is evident in the increasingly volatile tariff adjustment patterns shown in Figures 8 and 9, where both major economies and their trading partners engage in tit-for-tat policy moves.

This spiral emerges from several key mechanisms in the model:

1. **Strategic Retaliation**: When one economy raises tariffs, others respond in kind to protect domestic industries or as punitive measures. This is visible in the alternating patterns of positive and negative adjustments.

2. **Escalation Over Time**: The amplitude of tariff adjustments grows over time, with major economies making increasingly extreme moves (up to +10 and -5 percentage points), suggesting an escalating conflict.

3. **Asymmetric Power Dynamics**: Major economies show larger adjustment swings than trading partners, reflecting their greater economic leverage and willingness to use it aggressively.

Economic Consequences of Protectionism

The economic outcomes of this trade war dynamic are uniformly negative:

1. **Dramatic GDP Decline**: Both major economies and trading partners experienced substantial GDP contractions (75% and 63% respectively) over the simulation period. The smooth downward curve suggests cumulative, long-term damage rather than short-term shocks.
2. **Persistent Trade Volume Reduction**: The steady decline in trade volumes (approximately 29% for major economies and 28% for trading partners) represents a significant contraction in international economic activity.
3. **Inflationary Pressure**: Despite declining economic activity, inflation rates for major economies steadily increased, suggesting a troubling stagflationary outcome – the combination of economic stagnation with price inflation.

These results align with economic theory that suggests protectionist trade policies typically reduce overall economic welfare, even if they might provide short-term protection for specific industries or sectors.

Comparative Impact on Different Economic Groups

An important insight from the simulation is the differential impact on major economies versus trading partners:

1. **GDP Impact**: Major economies experienced a proportionally larger GDP decline (75% vs. 63%), suggesting that larger economies may actually suffer more in prolonged trade conflicts, possibly due to their greater dependence on global market access for growth.
2. **Tariff Rate Volatility**: Major economies exhibited greater tariff rate volatility and reached higher peak levels (up to 17% compared to 6% for trading partners), reflecting both their greater policy flexibility and potentially more aggressive stance.
3. **Response Patterns**: The shorter memory span of trading partners (2 periods vs. 4 for major economies) appears to result in more reactive, short-term policy adjustments, while major economies show evidence of more strategic, longer-term positioning.

Systemic Feedback Loops

The simulation reveals important systemic feedback mechanisms:

1. **Tariff-GDP Feedback**: Higher tariffs lead to lower GDP, which may incentivize further tariff increases as economies attempt to protect declining industries, creating a negative feedback loop.

2. **Trade Volume-Inflation Connection**: Declining trade volumes contribute to rising inflation, creating stagflationary pressure that complicates policy responses.
3. **Escalation-Retaliation Cycle**: The pattern of tariff adjustments shows clear evidence of retaliatory behavior, where increases by one group trigger responses by others, leading to escalation.

These feedback loops are particularly troubling because they suggest that once initiated, trade conflicts can become self-sustaining through endogenous mechanisms, making them difficult to resolve without coordinated policy intervention.

Conclusion

This simulation provides compelling evidence that aggressive tariff policies, similar to those implemented in recent years, can trigger a damaging cycle of retaliatory trade measures with severe negative consequences for the global economy. The results answer the key questions posed at the outset of this analysis:

1. **Impact on Initiating Economies**: Major economies that implement significant tariff increases suffer substantial economic damage, experiencing GDP declines that are proportionally larger than those of their trading partners, despite their greater economic power.
2. **Trading Partner Responses**: Trading partners consistently respond to tariff increases with retaliatory measures of their own, creating a self-perpetuating cycle of escalation.
3. **Global Trade Effects**: The cumulative effect is a significant decline in global trade volumes (approximately 28-29%), representing a substantial contraction in international economic activity.
4. **Trade War Dynamics**: The simulation confirms that these interactions can indeed lead to a full-fledged trade war with escalating tariffs, decreasing trade, declining GDP, and rising inflation – a situation where all participants lose.

The "trade war spiral" observed in this simulation is particularly noteworthy because it emerges organically from the fundamental economic relationships between tariffs, trade volumes, and GDP growth, rather than being explicitly programmed. This emergent behavior highlights how even rational actors pursuing what they perceive as their own interests can collectively create deeply suboptimal outcomes.

From a policy perspective, these findings suggest several important implications:

1. **Costs of Protectionism**: The long-term economic costs of protectionist policies likely outweigh any short-term benefits for specific protected sectors.

2. **Coordination Mechanisms**: International trade governance systems that facilitate coordination and prevent retaliatory spirals are crucial for maintaining economic stability.
3. **Policy Guardrails**: Implementing policy constraints that limit the magnitude of tariff adjustments could help prevent the extreme volatility observed in the simulation.

In conclusion, while tariffs may appear to be effective tools for addressing perceived trade imbalances or protecting domestic industries in the short term, this simulation demonstrates that their broader implementation can trigger systemic responses that ultimately harm all economies involved. The dramatic GDP declines and persistent stagflationary pressure observed in the model highlight the potential real-world risks of aggressive tariff policies and underscore the importance of international cooperation in trade relations.
